Estimation of Survival Function and Failure Rate

JAMMALAMADAKA S. RAO and R. C. TIWARI

University of California, Santa Barbara

Summary. The Bayesian estimation of the survival function and failure rate in the un-censored case has been treated in Proschan and Singpurwalla [5]. In this paper the extension of estimation to randomly censored data is considered. The time interval is partitioned into fixed class intervals. Assuming constant failure rate on these intervals and using a Dirichlet distribution as the prior, the resulting estimates of survival function and failure rate have nice and simple forms. If instead of the fixed time intervals, one uses the "natural" intervals formed by the observed failure times, this gives essentially the same result as in Ferguson and Proschan [3], Susarla and van Ryzin [7], but in a much simpler form. In this situation the limiting estimates are the Kaplan-Meier analog for the discrete situation (not the Kaplan-Meier product limit estimator (Kaplan and Meier [4])

Key words: Bayesian inference, Dirichlet distribution, survival function, failure rate.

1. Introduction

Let $T$ be a nonnegative random variable representing the failure time, with the distribution function $F$. The survival function $F$ is given by

$$\bar{F}(t) = P(T \geq t) = 1 - F(t - 0)$$

and the failure rate is given by

$$\lambda(t) = \lim_{h \to 0} \frac{1}{h} P(t \leq T < t + h \mid T \geq t),$$

if the limit exists. If $F$ is continuous with the density function $f$, then

$$\lambda(t) = \frac{f(t)}{F(t)}.$$

Notice in the literature $\lambda(t)$ is also called the hazard rate, force of mortality, and intensity rate. For a reference to the origin of these definitions see Barlow and Proschan [1].

Given a continuous failure time distribution $F$, consider a partition $\{(t_i, t_{i+1})\}_{i=0}^k$ of $(0, \infty)$ with $t_0 = 0$ and $t_{k+1} = \infty$. Consider a set of $N$ individuals. We take observations at the $k$ time points $t_1 \leq t_2 \leq \ldots \leq t_k$ (say at the end of each hour, day or

* Now at Indian Institute of Technology, Bombay, India.
similar period, not necessarily of equal lengths) and observe how many individuals failed and how many were censored (e.g., left the study) in each of these intervals. Let \( n_i \) denote the number of failures and \( m_i \) the number censored in the interval \((t_i, t_{i+1}]\), \( i = 0, 1, \ldots, k-1 \). For definiteness, we shall assume that those censored in the interval \((t_i, t_{i+1}]\) survived past \( t_{i+1} \). Without loss of generality, we can and shall assume that \( n_k = 0 \) and \( m_k = 0 \). Let \( n = \sum_{i=0}^{k-1} n_i, m = \sum_{i=0}^{k-1} m_i \) so that \( N = n + m \). Define 

\[
\begin{align*}
  n_{(i)} &= \sum_{j=i}^{k-1} n_j, \\
  m_{(i)} &= \sum_{j=i}^{k-1} m_j.
\end{align*}
\]

Then \( N_{(i)} = n_{(i)} + m_{(i)} \) is the number of individuals at risk at time \( t_i + 0 \); that is, whose failure or censoring time is at least \( t_i, i = 0, 1, \ldots, k-1 \).

For \( 0 \leq i \leq k \) define

\[
q_i = \frac{p_i}{(1 - p_0 - p_1 - \ldots - p_{i-1})}
\]

with \( q_0 = p_0 \). Clearly, \( q_k = 1 \). Holding \( f(t) = p_i/(t_{i+1} - t_i) \) constant over the interval \((t_i, t_{i+1}]\), the survival function and failure rate are given by

\[
\begin{align*}
  F(t) &= \left[ 1 - p_0 - \ldots - p_{i-1} \right] - \frac{(t-t_i)}{(t_{i+1} - t_i)} \frac{p_i}{(1 - q_i)} \\
  \lambda(t) &= \frac{q_i}{(t_{i+1} - t_i) - (t-t_i) q_i}, \quad t_i < t \leq t_{i+1}, \quad i = 0, 1, \ldots, k.
\end{align*}
\]

(1.2) (1.3)

Our problem is to estimate the survival function \( F(t) \) and the failure rate \( \lambda(t) \) defined in (1.2) and (1.3) respectively using the data on \( n = \{n_i\}_{i=0}^{k-1} \) and \( m = \{m_i\}_{i=0}^{k-1} \). We will denote this data by \( d \).

2. Bayes estimation of survival function and failure rate

A Bayesian considers \( q = \{q_i\}_{i=0}^{k} \) as a random vector and represents his/her opinion about \( q \) by a probability distribution, called a prior distribution, or simply, a prior. After observing the failure data \( d = (n, m) \), his/her opinion about \( q \), given the data \( d \), is called the posterior distribution. Let \( g \) be the prior density function of \( q \). The posterior density function of \( q \) given \( d \), namely \( g(q | d) \), is given by the relation

\[
g(q | d) \propto L(q | d) g(q),
\]

(2.1)

where \( L(q | d) \) is the likelihood function of \( q \) at the point \( d \), and the constant of proportionality which does not depend on \( q \) is \( \{fL(q | d) g(q) \, dq\}^{-1} \).
One usually employs a prior within a family $G$ of distributions, which is large enough to accommodate various shades of opinion about the parameter $q$. Further, if $g \in G$ is a prior for $q$, then the posterior $g(q \mid d)$ ought to be in a simple computable form. If $g(q \mid d) \in G$ for all $g \in G$ and for all data $d$, then $G$ is called a conjugate family of priors.

Observing that there is one-to-one correspondence between $p=(p_0, p_1, \ldots, p_k)$ and $q=(q_i)_{i=0}^k = (x_i)_{i=0}^k$ we define a conjugate family of priors for $p$ as follows. Let $\alpha = (x_i)_{i=0}^k$ be a sequence of finite non-negative numbers. We say the random vector $p$ has a $k$-dimensional Dirichlet distribution with parameter $\alpha$, and denote it by $p \sim D(\alpha)$, if the distribution of $(p_0, p_1, \ldots, p_k)$ is $D(x_0, x_1, \ldots, x_k) = D(x_0, x_1, \ldots, x_k) = D(x_0, x_1, \ldots, x_k)$ as defined in Wilks [8], Section 7.7.

Under the prior $D(\alpha)$ for $p$ the coordinates of random vector $q$ are independent, with $q_i$ having a Beta distribution with parameters $x_i$ and $x_{i+1}$ denoted by $\beta(x_i, x_{i+1})$, where $x_0 = \sum x_i$, $i = 0, 1, \ldots, k - 1$. After observing the data $d$ the likelihood function of $q$ at the point $d$ is

\[
L(q \mid d) = \prod_{i=0}^{k-1} q_i^{n_i} (1 - q_i)^{m_i} (1 - p_0 - p_1 - \ldots - p_k)^{m_0} \tag{2.2}
\]

Using (2.1) and (2.2) the posterior distribution of $q$ given the data $d$ is given by the relation

\[
g(q \mid d) \propto \prod_{i=0}^{k-1} q_i^{n_i + n_i - 1} (1 - q_i)^{m_i + n_i + m_0 - 1} \tag{2.3}
\]

The Bayes estimate of $q_i$ under prior $D(\alpha)$ (with respect to the squared error loss function) based on no sample, called the prior Bayes estimate of $q_i$, is

\[
\hat{q}^0_{i, \alpha} = E_{D(\alpha)}(q_i) = \frac{x_i}{x_i + \sum_{j=0}^{i-1} x_j + N_i} \tag{2.4}
\]

and based on the data $d$ is

\[
\hat{q}^N_{i, \alpha} = E_{D(\alpha)}(q_i \mid d) = \frac{x_i + n_i}{x_i + n_i + m_i + N_i} = \frac{x_i + n_i}{x_i + N_i}, \quad i = 0, 1, \ldots, k - 1. \tag{2.5}
\]

Clearly, from (2.4) and (2.5) we have

\[
\hat{q}^N_{i, \alpha} = w_i \hat{q}^0_{i, \alpha} + (1 - w_i) \hat{q}^0_{i, \alpha}, \tag{2.6}
\]

where $w_i = x_i / (x_i + N_i)$. Thus $\hat{q}^N_{i, \alpha}$ is a weighted mean of the prior Bayes estimate $\hat{q}^0_{i, \alpha}$ and the empirical estimate $\hat{q}^0_{i, \alpha} = n_i / N_i$ with weights $w_i$ and $(1 - w_i)$ respectively. Substituting $\hat{q}^N_{i, \alpha}$ and $\hat{q}^0_{i, \alpha}$ in equations (1.2) and (1.3), the Bayes estimates of $\hat{F}$ and $\hat{\lambda}$ for no sample size and with the data $d$ are respectively

\[
\hat{F}^0(t) = \left(1 - \frac{(t - t_i)}{(t_{i+1} - t_i)} \frac{x_i}{x_i + \sum_{j=0}^{i-1} x_j + N_i} \right) \prod_{j=0}^{i-1} \left(1 - \frac{x_j + n_j}{x_j + N_j} \right), \quad t_i < t < t_{i+1}, \tag{2.7}
\]

\[
\hat{F}^N(t) = \left(1 - \frac{(t - t_i)}{(t_{i+1} - t_i)} \frac{x_i + n_i}{x_i + n_i + m_i + N_i} \right) \prod_{j=0}^{i-1} \left(1 - \frac{x_j + n_j}{x_j + N_j} \right), \quad t_i < t < t_{i+1},
\]
and
\[
\begin{align*}
\lambda_i^0(t) &= \frac{x_i}{(t_{i+1} - t_i)(x_{i0} - (t_i - t_{i-1}) x_i)} \\
\lambda_i^N(t) &= \frac{x_i + n_i}{(t_{i+1} - t_i)(x_{i0}^N - (t_i - t_{i-1})(x_i + n_i))}, \quad t_i < t \leq t_{i+1}, \\
i &= 0, 1, \ldots, k - 1.
\end{align*}
\]

3. Limiting Bayes estimates

It appears that \(x_{i0}\), the sum of the parameters \(x_i\) and \(x_{i+1}\) of \(q_i\), enters into the expressions (2.4) and (2.5) as the ‘prior sample size.’ This has given rise to the general feeling that allowing \(x_{i0}\) to become small not only makes the ‘prior sample size’ small but also it corresponds to no prior information (see, for example, Ferguson [2], in the context of Dirichlet processes). By investigating the limit of the Bayes estimate of \(q_i\) when \(x_{i0}\) is allowed to converge to zero, we show below that it is misleading to think of \(x_{i0}\) as the prior sample size and the smallness of \(x_{i0}\) as having no information. (This result is discussed in Sethuraman and Tiwari [6] in the context of Dirichlet processes.)

Consider the convergent sequences of non-negative numbers \(\alpha = (x_i^r)_{i=0}^k, r = 0, 1, 2, \ldots\). If \(x_i^r \to x_i^0\) as \(r \to \infty\), then \(q_i^r \to q_i^0\), where for each \(r\), \(q_i^r = (q_i^r)^N\) is defined in (1.1) and \(\to\) represents convergence in distribution, and
\[
\begin{align*}
\hat{q}_i^0 &\to q_i^0, \\
\hat{q}_i^N &\to q_i^N, \quad i = 0, 1, \ldots, k - 1.
\end{align*}
\]
as \(r \to \infty\). Further, if we let \(x_{i0}\) converge to zero such that \(x_i^0/x_{i0}\) converges to a constant \(\theta_i, 0 < \theta_i < 1\), then in the limit as \(r\) tends to infinity \(q_i^0\) is the Binomial \((1, \theta_i)\) random variable; and
\[
\hat{q}_i^N \to n_i^N, \quad i = 0, 1, \ldots, k - 1.
\]
which is the empirical estimate \(\lambda_i, i = 0, 1, \ldots, k - 1\). Also, \(\hat{q}_i^N\) (which is as defined in (2.7) with \(\alpha\) replaced by \(\alpha^r\)) in the limit is the empirical estimate
\[
\hat{p}(r) = \left\{1 - \frac{(t_{i+1} - t_i)}{(t_{i+1} - t_{i-1})}ight\}^{n_i} \left(1 - \frac{n_i}{N_{i0}}\right)^{(t_i - t_{i-1})}, \quad t_i < t \leq t_{i+1}, \quad i = 0, 1, \ldots, k - 1.
\]

Let \(t_i^k\) denote the distinct observed failure times, again with \(t_0 = 0\) and \(t_{k+1} = \infty\). Let \(n_i\) denote the number of failures at \(t_i + 1\), \(i = 0, 1, \ldots, k - 1\), and let \(m_i, n_{i0}, m_{i0}\) and \(N_{i0}\) remain as before. We wish to partition the time-interval using these \(t_i^k\)'s, \(i = 1, 2, \ldots, k\), as before. This procedure is clearly justified when \(T\) is a discrete random variable and \(\{t_i^k\}_{i=1}^k\) is its support so that failures occur
only at these points. On the other hand, one may look at the case of continuous failure times as being approximated by a discrete situation like this where, because of observational restrictions, one observes the process at $t_{i+1}$ and makes the approximation that the $n_i$ failures in the interval actually occurred at $t_{i+1}$ instead of over the period $(t_i, t_{i+1})$, $i = 0, 1, ..., k-1$. This is analogous to the assumptions one makes in computing statistics like the mean and variance from continuous data that has been grouped into class intervals. It should be remarked that the procedure used by Susarla and Van Ryzin [7] amounts implicitly to such a partitioning of the time interval using the distinct observed failure times and using it to find the censoring numbers (cf. their section 3). In this case, the survival function and the failure rate are given by (cf. equations (1.2) and (1.3))

$$F(t) = \prod_{j=0}^{i} (1-q_j), \quad t_i < t \leq t_{i+1},$$  \hspace{1cm} (2.12)

and

$$\lambda(t) = \begin{cases} \frac{q_i}{0}, & t = t_{i+1}, \\ 0, & t_i < t < t_{i+1}, \end{cases} \quad i = 0, 1, ..., k. \hspace{1cm} (2.13)$$

Also, the Bayes estimates of $F$ and $\lambda$ are given by (cf. equations (2.7) and (2.8))

$$\hat{F}_B(t) = \prod_{j=0}^{i} \left(1 - \frac{n_j}{n_j + N_j} \right), \quad t_i < t \leq t_{i+1},$$  \hspace{1cm} (2.14)

and

$$\hat{\lambda}_B(t) = \begin{cases} \frac{n_i}{n_i + N_i} / (t_{i+1} - t_i), & t = t_{i+1}, \\ 0, & t_i < t < t_{i+1}, \end{cases} \quad i = 0, 1, ..., k-1. \hspace{1cm} (2.15)$$

Now an equation similar to (2.6) holds with $\lambda$ replaced by the Kaplan-Meier estimate $\hat{\lambda}_{KM}(t) = \frac{n_i}{N_i}$ at $t = t_{i+1}$. (Note that this not the usual Kaplan-Meier product limit estimate at $t = t_{i+1}$). Again, if $n_i \to 0$ and $n_i / N_i \to \theta_i$, $0 < \theta_i < 1$, in the sense discussed above, then the estimates (2.14) and (2.15) converge to

$$\hat{F}_{KM}(t) = \prod_{j=0}^{i} \left(1 - \frac{n_j}{N_j} \right), \quad t_i < t \leq t_{i+1},$$  \hspace{1cm} (2.16)

and

$$\hat{\lambda}_{KM}(t) = \begin{cases} \frac{n_i}{N_i}, & t = t_{i+1}, \\ 0, & t_i < t < t_{i+1}, \end{cases} \quad i = 0, 1, ..., k-1. \hspace{1cm} (2.17)$$
