

The effect of wind direction on ozone levels - a case study

S. Rao Jammalamadaka and Ulric J. Lund

University of California, Santa Barbara and California Polytechnic State University, San Luis Obispo

Abstract

This paper provides an illustrative case study on how the wind direction plays an important role in determining the ozone levels, in a suburb of Houston. Circular correlation and circular regression methods are used in the analysis and the primary goal is to illustrate how circular data analytic methods help in analyzing certain environmental issues.

Keywords: circular statistics; directional data; wind direction; ozone level.

1 Introduction

The wind direction, unlike many other linear variables such as the wind speed and ozone level, should be dealt with quite differently in statistical analyses. This is because a (2-dimensional) direction is a circular variable which can be represented as a point on the circumference of a circle. The numerical value assigned to it, and therefore the corresponding statistical analyses based on such numerical values, depend on what is taken to be the zero-direction and whether

a clockwise or anti-clockwise sense of rotation is used. Thus, in dealing with circular data like wind directions, one should be careful not to use the standard linear methods like the arithmetic mean and standard deviation, instead using measures and techniques which are independent of this arbitrary zero-direction and sense of rotation. The reader is referred to books such as Mardia and Jupp (2000) and Jammalamadaka and SenGupta (2001) for detailed descriptions of such methods. One of the aims of this paper is to increase such awareness by providing a case study that involves air pollutants and wind direction.

2 Data source

The Texas Natural Resource Conservation Commission (TNRCC) and local monitoring programs in Texas jointly collected air pollutant and weather data from 1972 to 1996. However, 1995 marked the last year that average wind directions and speeds were measured as well as ozone concentrations. Since the aim of our case study is to analyze the effect of wind direction on ozone levels, we chose 1995 as our study year. The raw data was obtained from the Internet (Texas Natural Resource Conservation Commission, 2003).

The 1995 TNRCC hourly data consists of the following variables: monitoring site; date, and time on a 24 hour scale; average ozone level, measured in parts per billion (ppb); average temperature, measured in degrees Fahrenheit; average wind direction, given in degrees clockwise from true north; average wind speed, in miles per hour.

There are 37 monitoring sites included in the 1995 TNRCC data set. Our focus was on the site located in Clute, Texas, due to its relative proximity to the Houston metropolitan area, and our interest in using circular statistics to assess the importance of wind speed and direction in transporting air pollutants. Figure 1 (Texas Natural Resource Conservation Commission, 2003) shows the

location of the Clute monitoring site, labelled as C11 on the map. It is situated approximately 50 miles south of Houston.

(Insert Figure 1 about here)

Since we had an abundance of data, we decided to omit hourly measurements for which either ozone or weather data was missing. This resulted in 7,608 hourly observations from January 1 to December 31, 1995, which we used in our analysis. Most analyses were done on the daily level. To this effect, the hourly data was averaged to obtain a daily data set as well, consisting of 317 observations for the year 1995. Daily average ozone level, temperature, and wind speed was computed using the usual sample mean for all non-missing hourly data. Daily average wind direction was computed using the sample mean direction (defined below).

3 Descriptive statistics and graphs

Table 1 presents some descriptive statistics for the daily air quality data set. Sample means and standard deviations are given for the linear variables, ozone level, temperature, and wind speed. The sample mean direction and sample circular dispersion were computed for the circular variable, wind direction.

The sample mean direction is computed by treating all angular measurements as points on the unit circle, and computing the resultant vector of the unit vectors determined by the data points. The sample mean direction is the direction of this resultant vector, and the the sample mean resultant length provides a measure of concentration of the circular data. That is, for a sample of n observations of a circular variable α , if we define

$$S = \sum_{i=1}^n \sin \alpha_i$$

$$C = \sum_{i=1}^n \cos \alpha_i$$

$$R = \sqrt{C^2 + S^2},$$

then the sample mean direction $\bar{\alpha}$ is the quadrant specific inverse tangent of S/R ,

$$\bar{\alpha} = \begin{cases} \arctan(S/C), & \text{if } C \geq 0, \\ \arctan(S/C) + \pi & \text{if } C < 0, \\ \text{Undefined}, & \text{if } R = 0. \end{cases}$$

The sample mean resultant length is given by $\bar{R} = R/n$. One commonly used measure of circular dispersion, also given in Table 1, is the circular variance defined as $1 - \bar{R}$. This statistic falls in the interval $[0, 1]$, taking values close to 0 when the data is highly concentrated around one direction, and close to 1 for widely dispersed data.

Returning to Table 1, we see that summer months with high average temperatures, generally also had high average ozone levels, though July had an unusually low ozone level. August and September saw the lowest average wind speeds, contributing perhaps to the summer months' high ozone readings.

Table 1: Descriptive statistics for daily data

Variable	Month												
	Annual	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Oct	Nov	Dec
Sample Size	317	19	12	27	30	27	30	30	31	30	30	20	31
Ozone Level													
Mean	28.23	21.15	27.82	28.28	31.05	22.13	38.5	23.02	33.16	38.37	31.98	16.71	19.44
S.D.	15.99	8.04	11.67	9.86	12.08	11.53	18.69	15.9	21.19	21.58	13.24	9.71	6.18
Temperature (Deg Fahrenheit)													
Mean	71.76	59.11	61.66	61.05	68.12	77.67	80.05	83.64	83.24	80.12	70.79	63.47	58.28
S.D.	11.39	7.73	6.15	8.18	6.24	3.51	3.26	2.38	1.43	5.75	4.41	8.34	12.58
Wind Speed (Mph)													
Mean	7.58	9.67	7.12	7.56	8.51	9.49	7.53	7.58	5.56	5.55	7.28	7.68	8.18
S.D.	2.90	4.32	2.39	2.36	2.99	2.78	2.71	3.12	1.74	1.63	2.49	2.66	2.58
Wind Direction (Deg Clockwise from North)													
Circ Mean	91.22	256.57	82.41	45.89	106.22	134.36	129.28	203.13	79.17	46.91	49.61	65.39	67.44
Circ Disp	0.70	0.79	0.60	0.70	0.43	0.17	0.65	0.62	0.54	0.47	0.41	0.61	0.82

Rose diagrams were created to further explore these variables one at a time (univariate) as well as in pairs (bivariate). Figure 2 shows a rose diagram of the average daily wind directions. The winds predominantly came from the east, northeast and southeast - onshore winds from the Gulf of Mexico.

(Insert Figure 2 about here)

When restricting to days on which the ozone level was above the 90th percentile, Figure 3 shows that winds were most frequently coming from the northern two quadrants. Winds were generally coming from the south on days for which the ozone level was below the 10th percentile, as shown in Figure 4. This may be evidence that indeed ozone was being transported from the Houston region, north of Clute.

(Insert Figures 3 and 4 about here)

Another view of the relationship between wind direction and ozone level is presented in Figure 5, where a rose diagram of the average daily wind directions

is labelled with the average ozone levels. Again, we see that when the wind came from the south, the ozone levels were lower, on average, than when the wind came from the north.

(Insert Figure 5 about here)

Similar graphs display average temperature and average wind speed by wind direction (Figures 6 and 7). We see that warmer days were associated with winds coming from the south, and these winds were also stronger, on average.

(Insert Figures 6 and 7 about here)

To discern how strong the bivariate relationships were, we used several measures of correlation, depending on what type of variables were considered. That is, different measures of correlation are necessary depending on how many of the two variables are circular variables (none, one, or both). We will refer to these three cases as the linear-linear, linear-circular, and circular-circular cases. For instance, examining the correlation between temperature and ozone level was done using the usual Pearson's correlation coefficient. However, correlation between ozone level and wind direction would necessitate a linear-circular statistic such as the one described in Mardia (1976).

Mardia defines this linear-circular correlation coefficient as the multiple correlation between a linear variable X and the sine and cosine of a circular variable α . The precise formula of the statistic is given by

$$r^2 = \frac{r_{xc}^2 + r_{xs}^2 - 2r_{xc}r_{xs}r_{cs}}{1 - r_{cs}^2},$$

where

$$r_{xc} = \text{corr}(x, \cos \alpha)$$

$$r_{xs} = \text{corr}(x, \sin \alpha)$$

$$r_{cs} = \text{corr}(\cos \alpha, \sin \alpha).$$

Two temporal variables indicating day of year and month of measurement were also coded and converted into circular variables. This was achieved by taking the day of the year and multiplying by $2\pi/365$, and taking month of the year and multiplying by $2\pi/12$. One measure of the association between wind direction and day or month would be the circular-circular correlation (Jammalamadaka and Sarma, 1988 and Section 8.2 of Jammalamadaka and SenGupta (2001)) between wind direction and the circular versions of day or month.

In general, the formula for the circular-circular correlation coefficient for n pairs of observations of two angular variables, α and β , with sample mean directions $\bar{\alpha}$ and $\bar{\beta}$, is given by

$$r_{c,n} = \frac{\sum_{i=1}^n \sin(\alpha_i - \bar{\alpha}) \sin(\beta_i - \bar{\beta})}{\sqrt{\sum_{i=1}^n \sin^2(\alpha_i - \bar{\alpha}) \sin^2(\beta_i - \bar{\beta})}}.$$

If α and β are independent, we would expect a value of $r_{c,n}$ close to 0. If the two angular variables are rotationally dependent, then we would expect a measure of $r_{c,n}$ close to ± 1 .

Table 2 presents a summary of the correlations computed for the average daily measurements. Temperature seems to have been the most seasonal variable, as exhibited by the strong linear-circular correlation between temperature and day/month. Ozone was most strongly correlated with wind speed. The negative correlation coefficient and the scatter plot smoother shown in Figure 8 indicate that lower ozone levels were associated with higher wind speeds. We saw above that stronger winds generally came from the south. Therefore, the negative correlation between wind speed and ozone level may again be due to the fact that Houston is located to the north of Clute.

Table 2: Bivariate correlation coefficients

	Ozone	Temperature	Wind Speed	Wind Direction
Temperature	0.17 ^a	-	-	-
Wind Speed	-0.38 ^a	0.02 ^a	-	-
Wind Direction	0.12 ^b	0.20 ^b	0.29 ^b	-
Month	0.05 ^b	0.67 ^b	0.09 ^b	-0.28 ^c
Day	0.06 ^b	0.71 ^b	0.08 ^b	-0.28 ^c

a Linear-linear correlation (Pearson's correlation coefficient)
b Linear-circular correlation (Mardia, 1976)
c Circular-circular correlation (Jammalamadaka and Sarma, 1988)

(Insert Figure 8 about here)

The relatively low correlations between wind direction and day/month are not surprising if we recall that the statistic computed measures the degree that two variables are related by a rotation, and we don't expect these variables to have such a relationship, but rather a seasonal fluctuation.

4 Regression models

Two regression models were fit using the Texas air quality data. One model used the daily measurements to predict ozone level from the remaining variables in the data set: temperature, wind speed, wind direction, month of measurement. This model had a linear response variable and a combination of two linear and one circular predictor variables. To also illustrate a regression model in which the response variable is circular, we chose to use the hourly data and modelled wind direction as a function of time of day.

Initially, a multiple linear regression model was used to predict ozone level from wind direction. This was a multiple linear regression, because to accommodate the circular covariate wind direction, we included the sine and cosine of wind direction as predictor variables, instead of the wind direction variable itself. A graph of ozone level versus wind direction, along with the fitted regression line, is given in Figure 9. Again, we can see that ozone levels were lowest on average when winds were coming from the southern quadrants (around π radians). However, there is still a substantial amount of unexplained variation ($R^2 = 0.12$) in the data, and we also see evidence of heteroscedasticity in this model fit.

(Insert Figure 9 about here)

By adding the other covariates, temperature, wind speed, and the seasonal component month, the amount of explained variation is more than doubled ($R^2 = 0.31$), yielding a significantly improved model fit ($p < 0.001$). The estimated regression coefficients for the model are given in Table 3. Here we see that increased temperatures were associated with higher ozone levels, and higher wind speeds were associated with lower ozone levels. The interpretation of the regression coefficients for the sine and cosine terms are not as transparent as for the linear predictor variables.

Table 3: Multiple regression predicting ozone level

Coefficient	Value	Std. Error	t-value	p-value
Intercept	-25.91	11.18	-2.32	0.0211
Temperature	0.88	0.15	5.75	0.0000
Wind Speed	-1.18	0.33	-3.61	0.0004
sin(Wind Dir)	2.74	1.23	2.22	0.0273
cos(Wind Dir)	11.30	1.60	7.05	0.0000
sin(Month)	7.23	1.76	4.11	0.0001
cos(Month)	2.75	1.85	1.49	0.1376

Next, for the purpose of illustrating the circular-circular regression model due to Jammalamadaka and Sarma (1993) (see also Section 8.6 of Jammalamadaka and SenGupta (2001)), we sifted through the data set to find a combination of circular variables that exhibited reasonable level of association. There was a strong relationship between hour of the day and wind direction during the days of June 7 through 10, 1995. For this subset of hourly data, the circular-circular correlation coefficient between wind direction and time of day was -0.67.

The regression model we are considering here essentially fits two trigonometric polynomials predicting the sine and cosine of the response variable, in this case wind direction. If we let θ denote the observed wind direction, and let α denote the hour the observation was taken, then the m^{th} order trigonometric polynomial predicting wind direction from time of day would fit the following two multiple linear regression models:

$$\cos(\theta) = \sum_{k=0}^m (A_k \cos k\alpha + B_k \sin k\alpha) + \epsilon_1,$$

$$\sin(\theta) = \sum_{k=0}^m (C_k \cos k\alpha + D_k \sin k\alpha) + \epsilon_2.$$

The appropriate order m of trigonometric polynomial is determined by testing the significance of the $m + 1^{st}$ terms in both regression models. If neither model requires the $m + 1^{st}$ terms, m^{th} order models are used.

Table 4: Circular-circular regression predicting wind direction

Coefficient	Response	
	cos(Wind Dir)	sin(Wind Dir)
Intercept	-0.8298	0.5317
1 st Order Terms		
cos(Hour)	0.0415	0.0587
sin(Hour)	-0.0895	-0.1335
P-Value for 2 nd Order	0.0156	0.0342
2 nd Order Terms		
cos(Hour)	-0.0055	0.0009
sin(Hour)	-0.0255	-0.0371
P-Value for 3 rd Order	0.3314	0.5045

For example, the first and second order models' regression coefficients are shown in Table 4, along with their p-values for assessing the need for higher order models. We can see that third order models are not necessary ($p = 0.3314$ and 0.5045), whereas there was a benefit to the second order model versus the first ($p = 0.0156$ and 0.0342). A graph of the data along with the first and second order models is presented in Figure 10.

(Insert Figure 10 about here)

5 Conclusion

Using published data on air pollutants and weather from the Texas Natural Resource Conservation Commission, it is shown here that the wind direction plays a significant role in how much ozone is transported from Houston, Texas to one of its neighboring towns. This case study illustrates the power of circular

data analytic tools in such environmental studies.

All calculations and graphs presented herein were obtained using S-PLUS 6.1 with the aid of the circular statistics library CircStats. CircStats is available for download from the Internet (Lund, 2003), and also is enclosed with the text by Jammalamadaka and SenGupta (2001).
