Odds Ratio Estimation in Bernoulli
Smoothing Spline ANOVA Models

Yuedong Wang *

Department of Biostatistics, University of Michigan

September 1, 1996

Abstract

Wahba et al (1995) introduced Smoothing Spline ANalysis of VAriance (SS ANOVA) method for data from exponential families. In this paper, we estimate the odds ratios based on a SS ANOVA model for binary data and construct Bayesian confidence intervals. We show the calculation using a real data set from Wisconsin Epidemiological Study of Diabetic Retinopathy. We conduct simulations to evaluate the performance of these estimates and their Bayesian confidence intervals. Our simulations suggest that the odds ratio estimates are quite reasonable in general but may be biased towards unity when comparing estimates at peaks with those in valleys. A bootstrap procedure is proposed to correct possible biases and it works very well in our simulation.

Key Words: bias correction; bootstrap; odds ratio; smoothing spline ANOVA.

1 SS ANOVA Models

Binary data occur very often in medical science and other areas. Suppose that for each individual, the response $Y$ takes two possible values: $Y = 0$ or $Y = 1$. Each individual is associated with a vector of covariates: $t = (t_1, \cdots, t_d)$. Let

$$ P(Y_i = 0|t_i) = 1 - p(t_i), \quad P(Y_i = 1|t_i) = p(t_i), \quad i = 1, \cdots, n. \quad (1) $$

Define the odds at $t$ as $p(t)/(1 - p(t))$. A logistic regression model

$$ \log \frac{p(t)}{1 - p(t)} = f(t) \quad (2) $$

is often used to investigate the relationship between the response probability $p(t)$ and the covariate vector $t$. Furthermore, a linear logistic regression model assumes that

$$ f(t) = C + \sum_{j=1}^{d} \beta_j t_j. \quad (3) $$

*Address for correspondence: Department of Biostatistics, University of Michigan, Ann Arbor, MI 48109, USA. E-mail: yuedong@umich.edu
That is, when other covariates are fixed, the effect of an increase in $t_j$ from $t_j^1$ to $t_j^2$ is to increase odds ratio by an amount $\exp(\beta_j(t_j^2 - t_j^1))$, which depends on the difference between $t_j^1$ and $t_j^2$ only. This model is easy to explain, but too restrictive in some applications. To build more flexible models than a linear regression surface, many authors used nonparametric methods. O’Sullivan, Yandell and Raynor (1986) and Gu (1990) used penalized likelihood method with smoothing splines and thin plate splines. Hastie and Tibshirani (1990) used additive models. Wahba, Wang, Gu, Klein and Klein (1995) introduced the SS ANOVA models using the penalized likelihood and Smoothing Spline ANalysis of VAriance methods. See also Wahba, Gu, Wang and Chappell (1994a), Wahba, Wang, Gu, Klein and Klein (1994b), Wang (1994), Wang, Wahba, Chappell and Gu (1995) and Wang, Wahba, Gu, Klein and Klein (1996) for details of the SS ANOVA models.

A SS ANOVA model assumes that $t_j \in \mathcal{T}(j)$, where $\mathcal{T}(j)$ is a measurable space. $f$ belongs to a subspace of tensor products of reproducing kernel Hilbert spaces (Aronszajn (1950), Wahba et al. (1995)). More precisely, the model space $\mathcal{M}$ of a SS ANOVA model contains elements

$$f(t) = C + \sum_{j \in J_0} f_j(t_j) + \sum_{(j_1, j_2) \in J_2} f_{j_1, j_2}(t_{j_1}, t_{j_2}) + \cdots$$

$$+ \sum_{(j_1, \cdots, j_d) \in J_d} f_{j_1, \cdots, j_d}(t_{j_1}, \cdots, t_{j_d}),$$

where $J_k$ is a subset of the set of all $k$-tuples $\{(j_1, \cdots, j_k) : 1 \leq j_1 < \cdots < j_k \leq d\}$ for $k = 1, \cdots, d$. Identifiability conditions are imposed such that each term in the sums is integrated to zero with respect to any one of its arguments. Each term in the first sum is called a main effect, each term in the second sum is called a two-factor interaction, and so on. Similar to the analysis of variance, usually higher-order interactions are eliminated from the model space to reduce the complexity of the model. See Wahba et al. (1995) for details of the model construction. When a model is chosen, we can regroup and write the model space as

$$\mathcal{M} = \mathcal{H}^0 \oplus \sum_{j=1}^q \mathcal{H}^j,$$

where $\mathcal{H}^0$ is a finite dimensional space containing functions which are not going to be penalized, usually lower order polynomials. A SS ANOVA estimate is the solution to the following variational problem:

$$\min_{f \in \mathcal{M}} \left\{-\sum_{i=1}^{n}(y_i f(t_i)) - \log(1 + e^{f(t_i)}) + \frac{n}{2} \sum_{j=1}^q \lambda_j \|P_j f\|^2\right\}.$$

The first part in (6) is the negative log likelihood. It measures the goodness of fit. In the second part, $P_j$ is the orthogonal projector in $\mathcal{M}$ onto $\mathcal{H}^j$ and $\|P_j f\|^2$ is a quadratic roughness penalty. $\lambda_j$’s are a set of smoothing parameters. They control the trade-off between the goodness of fit and the roughness of the estimate. See Wahba et al. (1995) and Wang et al. (1995) for details of how to calculate a SS ANOVA estimate and how to choose smoothing parameters based on data.
The solution to (6) is approximately equal to the posterior mean of the following Bayesian model. Let the prior for \( f(t) \) be

\[
F_\xi(t) = \sum_{\nu=1}^{M} \tau_\nu \phi_\nu(t) + b^2 \sum_{\beta=1}^{q} \sqrt{\theta_\beta} Z_\beta(t),
\]

(7)

where \( \tau = (\tau_1, \ldots, \tau_M)^T \sim N(0, \xi I) \), \( Z_\beta \) are independent, zero mean Gaussian stochastic processes, independent of \( \tau \), with \( EZ_\beta(t)Z_\beta(s) = R_\beta(t, s) \). \( R_\beta \) is the reproducing kernel of \( \mathcal{H}_\beta \). With \( \xi \to \infty \), Wahba et al. (1995) proved that the posterior means of the overall function and its components are approximately equal to the solution to (6) and its components. Posterior covariances are listed in Theorem 1 in Wahba et al. (1995). These posterior covariances can be used to construct Bayesian confidence intervals for a SS ANOVA estimate and its components.

2 Estimation of Odds Ratios and Bias Correction

The SS ANOVA estimate of the probability function for binary data can be used to calculate the odds ratios. For any two points \( t \) and \( s \), the odds ratio of \( t \) and \( s \) equals

\[
OR(t/s) = \exp\{f(t) - f(s)\},
\]

(8)

where the function \( f \) is the logit of the probability function. It depends on both \( t \) and \( s \) since we do not assume a linear relationship. A natural estimate of \( OR(t/s) \) is

\[
\hat{OR}(t/s) = \exp\{\hat{f}(t) - \hat{f}(s)\}.
\]

(9)

Often, we are interested in how one covariate affects the odds when other risk factors are fixed (at their medians or means). Suppose the covariate we are interested in is \( t_1 \). For any two possible values \( t_1^1 \) and \( t_1^2 \) of \( t_1 \), the log odds ratio of \( t = (t_1^2, t_2, \ldots, t_d) \) and \( s = (t_1^1, t_2, \ldots, t_d) \) equals

\[
\log(\hat{OR}(t/s)) = \sum_{i \in J_1} (f_i(t_1^2) - f_i(t_1^1)) + \sum_{(1,j) \in J_2} (f_{1,j}(t_1^2, t_j) - f_{1,j}(t_1^1, t_j))
\]

\[
+ \sum_{(1,j_2,\ldots,j_d) \in J_d} (f_{1,j_2,\ldots,j_d}(t_1^2, t_{j_2}, \ldots, t_{j_d}) - f_{1,j_2,\ldots,j_d}(t_1^1, t_{j_2}, \ldots, t_{j_d})).
\]

Notice that the odds ratio depends on \( t_j, j = 2, \ldots, d \), if there is an interaction between \( t_1 \) and \( t_j \) in the model space \( \mathcal{M} \).

Often, the SS ANOVA estimate of the probability function has relatively large biases at peak and valley points. These biases are added up if we pick \( t_1^1 \) at a peak and \( t_1^2 \) at a valley. This effect is obvious from the simulations in section 4. Correction of the possible biases is necessary for these cases. We propose a bootstrap procedure to correct these biases: (1) generate bootstrap samples of binary data from SS ANOVA estimate of the probability function \( p \); (2) calculate SS ANOVA estimates of odds ratios from these bootstrap samples and denote the median of them as \( \hat{OR}^*(t/s) \); (3) estimate the bias of log odds
ratio by \( \hat{\text{bias}} = \ln \hat{O}_R(t/s) - \ln \hat{O}_R^*(t/s) \); (4) calculate the bias corrected estimate by 
\( \hat{O}_R_{\text{corrected}}(t/s) = \exp(2\hat{O}_R(t/s) - \hat{O}_R^*(t/s)) \). Similar bias correction in nonparametric regression setting using bootstrap has been studied previously by Gu (1987) and Fan and 
Hu (1992). These studies are primarily theoretical and it is not clear whether this technique will necessarily work in practice. Simulation in section 4 indicates that this procedure works very well.

Based on the same Bayes model (7), we can approximate the posterior distribution of 
\( f(t) - f(s)\mid y \) by a Gaussian distribution with mean \( \hat{f}(t) - \hat{f}(s) \) and variance

\[
\delta^2 = \text{Var}(f(t) - f(s) \mid y) = \text{Var}(f(t) \mid y) + \text{Var}(f(s) \mid y) - \text{Cov}(f(t), f(s) \mid y).
\]

(10)

\( \delta^2 \) can be calculated from the formulas in Theorem 1 in Wahba et al. (1995). See Wang (1997) for details for calculations of posterior covariances. Hence we can approximate the distribution of \( OR(t/s) \) by a log Normal distribution and construct the \( (1 - \alpha) \times 100\% \) Bayesian confidence interval as

\[
(\hat{O}_R(t/s) \exp\{-z_{\alpha/2}\}, \hat{O}_R(t/s) \exp\{z_{\alpha/2}\}).
\]

(11)

It is well established that the Bayesian confidence intervals for the function \( f \) have good frequentist properties (Wahba 1983, Nychka 1988, Wang and Wahba 1995). It is not clear whether the Bayesian confidence interval (11) for the odds ratio has similar frequentist properties since it involves two points. Our simulations in section 4 indicate that the answer is yes.

3 A Practical Example

In this section, we use a data set from the Wisconsin Epidemiology Study of Diabetic Retinopathy (WESDR) to demonstrate the SS ANOVA method and odds ratio estimation. See Klein, Klein, Moss, Davis and DeMets (1988), Klein, Klein, Moss, Davis and DeMets (1989) and references therein for a detailed description of the data and some analyses using the linear logistic regression.

In brief, the data set contains 256 insulin-dependent diabetic patients diagnosed as having diabetes before 30 years of age ("younger onset group"). None of them had diabetic retinopathy at the baseline. At the follow-up examination, all 256 patients were checked to see if they had diabetic retinopathy. The response \( Y = 1 \) if an individual had diabetic retinopathy at the follow-up. \( Y = 0 \) otherwise. Several covariates were recorded. We only list the variables pertinent to our analyses:

1. age: age in years at the time of baseline examination;
2. duration: duration of diabetes at the time of baseline examination;
3. glycosylated hemoglobin: a measure of hyperglycemia;
4. Systolic blood pressure in mmHg.
Following model was used in Wang (1994) (Model IV):

\[
\text{logit}(P(\text{age, duration, glycosylated hemoglobin, pressure})) = \mu + f_1(\text{age}) + a_1 \times \text{duration} + a_2 \times \text{glycosylated hemoglobin} + a_3 \times \text{pressure}.
\]  

(12)

Figure 1: Left: estimates of the main effects \(f_1(\text{age})\). Right: estimates of odds ratios \(OR(\text{age}/\text{age} = 25)\). Dashed lines are 90% Bayesian confidence intervals.

The main effect of \(\text{age}\) is plotted in the left panel of Figure 1. We see that patients with age from 20 to 30 are at higher risk. To compare the risk at some particular ages, one may want to calculate the odds ratios at these ages. Suppose we fix \(\text{duration, glycosylated hemoglobin}\) and \(\text{pressure}\) at their median values, and pick \(\text{age} = 25\) as the base and compare its risk to other ages. The estimated odds ratios and their 90% Bayesian confidence intervals are plotted in the right panel of Figure 1. We see that the odds at \(\text{age} = 25\) is significantly higher than the odds at \(\text{age} \leq 13\).

From Figure 1, the odds at \(\text{age} = 25\) is not significantly higher than the odds at \(\text{age} = 40\). But since \(\text{age} = 25\) is a peak point, it is likely that \(\hat{OR}\) overestimates the true \(OR\). This is supported by our simulation in section 4, where \(\hat{OR} = .45\) and \(\hat{OR^*} = .73\) in Table 1. We can estimate the bias of log odds by \(\text{bias} = \ln \hat{OR} - \ln \hat{OR^*} = \ln .45 - \ln .73 = -.48\). Then we can correct this bias in the original estimate: \(\hat{OR}_{\text{corrected}} = .45 \times \exp(-.48) = .28\). The 95% Bayesian confidence interval for the corrected estimate of odds ratio becomes (.07,1.00), which is just significant.

4 Simulations

We conducted three simulations to evaluate the performance of the estimates of the odds ratios and their Bayesian confidence intervals. We also conduct a simulation to evaluate the
performance of the bias correction procedure.

In the first two simulations, we used two univariate logit functions:

\[
\text{Case A} \quad f(t) = \frac{1}{2}\beta_{10.5}(t) + \frac{1}{2}\beta_{7.7}(t) + \frac{1}{2}\beta_{5.10}(t) - 1, \\
\text{Case B} \quad f(t) = 3[10^5t^{11}(1 - t)^6 + 10^3t^3(1 - t)^{10}] - 2,
\]

where \(0 \leq t \leq 1\). \(\beta_{p,q}\) is the Beta function: \(\beta_{p,q}(t) = \frac{\Gamma(p+q)}{\Gamma(p)\Gamma(q)}t^{p-1}(1 - t)^{q-1}\). The true probability functions of these two cases are plotted in Figure 2. Bernoulli responses \(y_i\) were generated on grid points \(t_i = (i - 0.5)/n, \ i = 1, \cdots, n\), according to the true probability function, where \(n\) is the sample size. Two sample sizes are used: \(n = 100\) and \(n = 200\). In Case A, we use \(t = 0.2\) as the base and calculate odds ratios at points \(t = 0.4, t = 0.6, t = 0.8\) and \(t = 1\). In Case B, we use \(t = 0.5\) as the base and calculate odds ratios at points \(t = 0.1, t = 0.2, t = 0.3\) and \(t = 0.4\).

![Figure 2: Plots of probability functions used in the first two simulations.](image)

In the third simulation, we use the estimated probability function of (12) as the true model. The design is the same as the data. We call it Case C. As in the above odds ratio calculations, we use \(\text{age} = 25\) as the base and calculate odds ratios at points \(\text{age} = 10, \text{age} = 15, \text{age} = 35\) and \(\text{age} = 40\).

We repeated all three simulations 100 times. In Table 1, the true odds ratios are listed in rows as \(OR\); medians of the 100 estimates of the odds ratios and the standard deviations are listed in the rows labeled \(\hat{OR}\) with standard deviations inside parentheses; the number of times in the 100 replications that the 90% and 95% Bayesian confidence intervals covered the true odds ratios are listed in the rows labeled Coverage with the 95% coverage number inside parentheses. We conclude from this table that these odds ratio estimates and their

</table>

Bayesian confidence intervals work well. Estimates of OR’s are generally biased toward unity if one of the two points of OR is at the peak and/or the other is at the valley (for instance, .4/.2 from Case A). This is because the SS ANOVA estimate \(\hat{f}\) may underestimate \(f\) at a peak and overestimate \(f\) at a valley. The coverages of Bayesian confidence intervals at high bias points are lower than the nominal value, while the coverages are higher at other points. So these Bayesian confidence intervals behave similarly to the Bayesian confidence intervals for the estimates of probabilities on the logit scale.

To evaluate the performance of bias correction procedure, we use Case C as our true model. At each of 100 replications, bootstrap bias correction procedure with 100 bootstrap samples is used to get bias corrected estimates of odds ratios. Figure 3 shows the true odds ratio function (solid line), the average of the odds ratio estimates (dotted line) and the average of bias corrected odds ratio estimates (dashed line). The bootstrap correction procedure works very well.
